Abstract. The endogenous biosynthesis of the quinone nucleus of coenzyme Q₁₀ (CoQ₁₀) from tyrosine is dependent on adequate vitamin B₆ nutriture. Lowered blood and tissue levels of CoQ₁₀ have been observed in a number of clinical conditions. Many of these clinical conditions are most prevalent among the elderly. Kalen et al. have shown that blood levels of CoQ₁₀ decline with age. Similarly, Kant et al. have shown that indicators of vitamin B₆ status also decline with age. Blood samples were collected from 29 patients who were not currently being supplemented with either CoQ₁₀ or vitamin B₆. Mean CoQ₁₀ concentrations was 1.1 ± 0.3 μg/ml of blood. Mean specific activities of EGOT was 0.30 ± 0.13 μmol pyruvate/hr/10⁸ erythrocytes and the mean percent saturation of EGOT with PLP was 78.2 ± 13.9%. Means for all parameters were within normal ranges. Strong positive correlation was found between CoQ₁₀ and the specific activity of EGOT (r = 0.5787, p < 0.001) and between CoQ₁₀ and the percent saturation of EGOT with PLP (r = 0.4174, p < 0.024). Studies are currently in progress to determine the effect of supplementation with vitamin B₆ of blood CoQ₁₀ levels. It appears prudent to recommend that patients receiving supplemental CoQ₁₀ be concurrently supplemented with vitamin B₆ to provide for better endogenous synthesis of CoQ₁₀ along with the exogenous CoQ₁₀.

1. Introduction

In 1983, Olson and Rudney [1] reviewed the work which led to the elucidation of the biosynthetic pathway for coenzyme Q (Fig. 1). Most higher organisms have lost the ability to produce non-steroidal aromatic compounds from simple precursors. They, instead, rely on dietary precursors for aromatic compounds. Coenzyme Q (CoQ) biosynthesis begins with the conversion of tyrosine to 4-hydroxybenzoic acid. 4-Hydroxybenzoic acid is the key precursor to the benzoquinone nucleus of CoQ. The isoprenoid side chain is added at the next step and its length is variable according to species. Humans and most mammals synthesize CoQ₁₀.

Vitamin B₆, as pyridoxal 5'-phosphate (PLP), is required for the initial transamination step which produces 4-hydroxyphenylpyruvic acid from tyrosine. Thus, an adequacy of vitamin B₆ nutriture is essential for the synthesis of CoQ.

Lowered blood and tissue levels of CoQ₁₀ have been observed in a number of clinical conditions. Many of these clinical conditions are most prevalent among the elderly. Kalen et al. [2] have shown that blood levels of CoQ₁₀ decline with age. As can be seen in Fig. 2, the CoQ content of rat tissues peaks in early adulthood and, with the exception of heart tissue, declines dramatically with age. The tissues levels of CoQ in 300 day old rats declined 72.3% in lung, 47.0% in spleen, 72.9% in liver and 56.5% in kidney from the levels found in 30 day old rats. (Heart increased 7.5%).
Fig. 1. Biosynthetic pathway for coenzyme Q in higher organisms. From [1].

Coenzyme Q<sub>9</sub> Content of Rat Tissues with Age

Fig. 2. Effect of age on tissue content of coenzyme Q<sub>9</sub> in rats.

Figure 3 shows that CoQ declines substantially in human tissues with age from a high in early adulthood. The tissue levels of CoQ in 77–81 year olds declined 48.3% in lung, 57.1% in heart, 60.1% in spleen, 17.0% in liver and 34.7% in kidney from the levels found in 19–21 year olds.

Similarly, Kant et al. [3] have shown that indicators of vitamin B<sub>6</sub> status also decline with age (Fig. 4). The mean plasma PLP for the 25–35 year age group was 76 ± 6 nmol/l as compared to 42 ± 6 nmol/l for the 65–75 year group. This represents a decrease of 44.7%.
The Food and Nutrition Board of the US National Academy of Sciences also reports [4] a decline in dietary intakes of vitamin B6 with advancing age. The Recommended Dietary Allowance (RDA) for vitamin B6 is 1.0 mg for young children, 2.0 mg for adult men and 1.6 mg for adult women. The Food and Nutrition Board reports that, on the average, young children exceed the RDA at 1.2 mg/day while adults fall short of the RDA at 1.9 mg for men and 1.2 mg for women.

As an added concern, the US intake of protein is substantially higher than the Recommended Dietary Allowance at every age group. This increases the need for vitamin B6 even further. Average protein intakes in the US are 50 g/day in young children, 110 g/day in men and 70 g/day in women as compared to the RDAs of 24 g/day, 58 g/day, and 44 g/day, respectively.

Since both CoQ10 levels and vitamin B6 levels are known to decrease with age and since vitamin B6 is essential for the biosynthesis of CoQ10, it is possible that the age related decline in CoQ10 levels is due, at least in part, to poor vitamin B6 status. Alternatively, it is possible that the age related declines of the two substances are merely coincidental and not directly related to one another. As an initial step in defining the nature of the relationship, a study was undertaken to determine if there was a correlation between blood levels of CoQ10 and vitamin B6 status in a group of patients and healthy subjects submitting samples to our laboratory. If a correlation is found to exist, further studies would be warranted.

2. Methods

Blood samples were collected from 29 patients and healthy subjects. None of the participants were receiving supplements of either CoQ₁₀ or vitamin B₆ at the time of blood collection. Samples were analyzed for CoQ₁₀ by HPLC using a slight modification of the procedure of Lang et al. [5]. Vitamin B₆ status was estimated as specific activity of erythrocyte glutamic-oxaloacetic transaminase (EGOT) by the procedure of Kishi and Folkers [6]. Data analyses were performed using SPSS for the Macintosh [7].

3. Results and discussion

Blood samples from 29 patients and healthy volunteers were analyzed for their content of CoQ₁₀ and for specific activities of EGOT, an indicator of vitamin B₆ status. Subjects ranged in age from 23 to 66 years. None of the subjects was currently receiving either vitamin B₆ or CoQ₁₀ supplements. The results are displayed in Table 1. As can be seen, the mean CoQ₁₀ level (1.1 ± 0.3 µg/ml) was within the expected normal range. The mean specific activity (–PLP) for EGOT was 0.30 ± 0.13 µmol pyruvate/hr/10⁸ erythrocytes which is at the lower end of the normal range. The mean specific activity after addition of PLP (+PLP) was 0.37 µmol pyruvate/hr/10⁸ erythrocytes indicating that the system was 78.9% saturated. EGOT is an inducible enzyme. With vitamin B₆ supplementation, specific activities of 0.70 are often seen with 100% saturation.

Correlational analyses revealed a strong positive correlation between blood levels of CoQ₁₀ and the specific activity of EGOT (r = 0.5787, p < 0.001) and between CoQ₁₀ and the percent saturation of EGOT with PLP (r = 0.4174, p < 0.025). The finding may be of clinical importance. If, as the biochemistry of the synthetic pathway suggests, a person’s vitamin B₆ nutriture affects the endogenous biosynthesis of CoQ₁₀ then both a possible mechanism for lowered CoQ₁₀ levels in blood and tissue of some patients and a mechanism for improving these levels may exist.

4. Conclusions

Studies are currently in progress in our laboratories to determine the effect of supplementation with vitamin B₆ of blood CoQ₁₀ levels. Until those results are available, it appears prudent to recommend that patients receiving supplemental CoQ₁₀ be concurrently supplemented with vitamin B₆ to potentially provide for better endogenous synthesis of CoQ₁₀ along with the exogenous CoQ₁₀.
